V.A.V., K.T., A.S.H. and G.K. are members of the guideline development group, with technical support provided by M.F.M.M.

This is an updated guideline prepared for the British Association of Dermatologists’ (BAD) Clinical Standards Unit, made up of the Therapy & Guidelines (T&G) Subcommittee. Members of the Clinical Standards Unit are: J.R. Hughes (Chairman T&G), J. McLelland, A.J. McDonough, S. Punjabi, D.A. Buckley, I. Nasr, V.J. Swale, C.E. Duarte Williams, P.M. McHenry, S. Wagle (British National Formulary), S. Amin (British National Formulary), R. Davis (British Dermatological Nursing Group), S.E. Haveron (BAD Scientific Administrator), M.F. Mohd Mustapa (BAD Clinical Standards Manager).

Guidelines produced in 2002 by the British Association of Dermatologists; reviewed and updated 2012.

DOI 10.1111/bjd.12072

1.0 Purpose and scope

The overall objective of the guideline is to provide up-to-date, evidence-based recommendations for the management of bullous pemphigoid (BP). The document aims to update and expand on the previous guidelines by: (i) offering an appraisal of all relevant literature since January 2002, focusing on any key developments; (ii) addressing important, practical clinical questions relating to the primary guideline objective; (iii) providing guideline recommendations and, where appropriate, with some health economic implications discussing potential developments and future directions.

The guideline is presented as a detailed review with highlighted recommendations for practical use in the clinic (see section 14.0), in addition to an updated patient information leaflet [available on the British Association of Dermatologists’ (BAD) website; http://www.bad.org.uk].

2.0 Stakeholder involvement and peer review

The guideline development group consisted of consultant dermatologists. The draft document was circulated to the BAD membership, the British Dermatological Nursing Group (BDNG), the Primary Care Dermatological Society (PCDS) and the Pemphigus Vulgaris Network for comments, and was peer reviewed by the Clinical Standards Unit of the BAD (made up of the Therapy and Guidelines subcommittee) prior to publication.

3.0 Methodology

This set of guidelines has been developed using the BAD’s recommended methodology1 and with reference to the Appraisal of Guidelines Research and Evaluation (AGREE II) instrument.2 Recommendations were developed for implementation in the National Health Service (NHS) using a process of considered judgment based on the evidence. PubMed, MEDLINE and EMBASE databases were searched up to June 2012 for meta-analyses, randomized and nonrandomized controlled clinical trials, case series, case reports and open studies involving bullous pemphigoid, with no language exclusions; search terms and
strategies are detailed in Appendix S1 online (see Supporting information).

Additional relevant references were also isolated from citations in the reviewed literature, as well as (independent) targeted searches carried out by coauthors. Working in pairs, the authors screened the identified titles, and those relevant for first-round inclusion were selected for further scrutiny. The abstracts for the shortlisted references were then reviewed and the full papers of relevant material were obtained; disagreements in the final selections were resolved by discussion with the entire development group. Additional selection criteria included relevant publications on the management of childhood BP.

The structure of the 2002 guidelines was then discussed and re-evaluated, and different coauthors were allocated separate subsections. Each coauthor then performed a detailed appraisal of the selected literature with discussions with the entire development group to resolve any issues, e.g. with the quality of evidence and making the appropriate recommendations. All subsections were subsequently collated and edited to produce the final guideline.

4.0 Limitations of the guidelines

This document has been prepared on behalf of the BAD and is based on the best data available when the document was prepared. It is recognized that under certain conditions it may be necessary to deviate from the guidelines and that the results of future studies may require some of the recommendations herein to be changed. Failure to adhere to these guidelines should not necessarily be considered negligent, nor should adherence to these recommendations constitute a defence against a claim of negligence.

5.0 Plans for guideline revision

The proposed revision date for this set of recommendations is scheduled for 2017; where necessary, important interim changes will be updated on the BAD website.

6.0 Background

6.1 Definition

BP is an autoimmune subepidermal blistering disease that typically affects the elderly but may rarely present in children and younger adults. Autoantibodies of IgG type (and less commonly IgA, IgM and IgE) attack components of the adhesion complex of the basement membrane zone (BMZ) and result in subepidermal blistering. The two main autoantigens are BP230 (BPAG1) and BP180 (BPAG2, collagen XVII).

6.2 Epidemiology

BP is the most common immunobullous disease in Western Europe with a reported incidence of 43 per million per year in the U.K. and 7–13 per million per year in other parts of Europe. The mean age of onset is around 80 years. Recently it has been shown that BP is associated with neurological disease such as cerebrovascular disease, dementia, Parkinson disease, epilepsy and multiple sclerosis. These conditions pre-date BP and hence are considered as risk factors. There are a number of anecdotal case reports suggesting an association between BP and some drugs. A recent small case series reported BP occurring in five diabetic patients taking an oral hypoglycaemic agent, glitin (dipeptidyl peptidase-IV inhibitor), together with metformin. To date there are three epidemiological studies on the subject of BP and drugs. Two French case–control studies, both by the same author, have described a significant relationship with the use of spiranolactone and neuroleptics. A recent U.K. case–control study found an association only with furosemide after adjusting for cardiovascular and neurological disease. The mechanism by which drugs may induce BP has not been studied. There is no conclusive evidence for an association with malignancy or other autoimmune diseases.

6.3 Clinical presentation

Tense blisters are often seen on erythematous or normal-looking skin of limbs and trunk and may be widespread or localized. Bullae and/or erosions may be present in the oral and genital mucosa. Pruritus alone or associated with erythema and/or urticated plaques may precede formation of bullae by weeks or months; in some cases bullae may not become clinically apparent.

7.0 Diagnosis

7.1 Laboratory diagnosis of bullous pemphigoid

A skin biopsy from a fresh blister stained with haematoxylin and eosin shows subepidermal cleavage and an inflammatory infiltrate mainly consisting of eosinophils; however, the diagnosis is confirmed with immunofluorescence studies (IF). A biopsy for direct IF (DIF) is taken from uninvolved skin about 1 cm away from a fresh blister and is immediately snap-frozen in liquid nitrogen or transported in either Michel’s transport medium or normal (0.9%) saline. If using saline, the biopsy must be processed within 24–48 h; with Michel’s medium prompt handling is to be preferred, but a longer delay of up to 2 weeks may still yield results. Indirect IF (IIF) is performed on serum, and if this is not obtainable, on blister fluid. The characteristic DIF picture in BP is a linear deposition of IgG and/or C3 along the BMZ. Other immunoglobulins, including IgA, IgM and IgE, may also be present. Substrates used for IIF include monkey oesophagus and normal human skin; the latter can be split using molar saline. Antibodies in BP serum usually detect antigens at the roof of the salt-split skin. In most cases this may help to differentiate BP from other immunobullous diseases such as epidermolysis bullosa acquisita (EBA) and some cases of mucous membrane pemphigoid (MMP), in both of which antibodies are deposited on the dermal aspect of the split skin.
Over recent years, enzyme-linked immunosorbent assay (ELISA) has emerged as an additional diagnostic technique for some autoimmune bullous diseases. Serum levels of antibodies to both BP180 and BP230 can be measured with commercially available ELISA kits, with the BP180 ELISA being more sensitive than the BP230 ELISA. The NC16A domain is an important pathogenic epitope of the BP180 antigen and is used in BP180 ELISA to detect antibody titres that reportedly correlate with disease activity. In one study, false-positive ELISA results using the same commercial kits were reported in 7–4% of sera with negative IIF. The ELISA is currently not widely available in the U.K. but is a useful additional diagnostic tool in selected cases and in research. IF studies remain the gold standard for diagnosis.

7.2 Differential diagnosis

Autoimmune bullous diseases may overlap in morphology and immunopathology; however, factors such as age of onset, course of the disease, absence of scarring and extent of mucosal involvement are important in differentiating the diagnosis. DIF and salt-split IIF are useful in distinguishing BP from other subepidermal diseases, namely linear IgA disease, MMP and EBA.

Blisters occur in genetic bullous diseases, in particular the epidermolysis bullosa group and may also be caused by insect bites, burns, oedema, cellulitis, erythema multiforme and contact dermatitis. Viral and bacterial skin infections should be recognized and treated before treatment with immunosuppressant therapy is initiated.

8.0 Management

BP is usually a self-limiting disease with a clinical course that may last from months to years. During the active stage, the disease is associated with significant morbidity and a mortality twice that of the general elderly population. Older age at onset and frail general condition are poor prognostic factors. Many available treatments are associated with toxicity and may be poorly tolerated in patients with BP. Mortality during the first year is significantly higher in patients treated with high doses of systemic corticosteroids (prednisolone equivalent >40 mg daily). Treatment should aim to control symptoms with minimum adverse effects where possible. Options are broadly divided into anti-inflammatory drugs, immunosuppressive or immunomodulating drugs, and procedures aiming to remove circulating pathogenic antibodies and inflammatory mediators. The choice of treatment depends on the individual patient’s circumstances especially the severity of the BP and the presence of comorbidities.

For the definitions of the strength of recommendations and levels of evidence see Appendix 1.

8.1 Systemic steroids (strength of recommendation A; level of evidence 1+)

Systemic corticosteroid therapy was demonstrated to be effective in BP in uncontrolled clinical studies during the 1950s and has become established as the mainstay of treatment. The effect in most cases is rapid, with suppression of inflammation and blistering typically achieved within 1–4 weeks, after which the dose is gradually reduced. The most commonly used drugs are prednisone and prednisolone which are assumed to be bioequivalent. Serious dose-dependent metabolic and immunosuppressive adverse effects were recognized in these original studies and in the four randomized controlled trials (RCTs) involving systemic steroids in the treatment of BP listed in Table 1.

The effect of very high doses of systemic steroid was assessed in eight patients with severe widespread BP, of whom six had failed to respond to standard doses of systemic steroid. Seven of the eight had significant medical comorbidity. Intravenous methylprednisolone, either 1 g daily (two patients), or 15 mg kg<sup>−1</sup> daily (six patients) for 3 days, was followed by prednisone 30–40 mg daily. All patients responded rapidly to the intravenous methylprednisolone, but in spite of the oral prednisone, blistering (albeit less severely than initially) recurred within 2 weeks. One patient died within 1 week of the intravenous methylprednisolone, and three died between 1 and 4.5 months following the treatment. The causes of death were cardiac arrest, infection and congestive cardiac failure.

General conclusions from the studies are:

1. Systemic steroids are the best established treatment for BP;
2. Immunosuppressive and metabolic adverse effects occur and are dose-dependent;
3. Doses of prednisolone of 0.75–1.0 mg kg<sup>−1</sup> daily in widespread BP are effective within 1–4 weeks in about 60–90% of cases.

Clinical experience suggests that the more severe the disease, the larger the dose of steroid is required (up to 1 mg kg<sup>−1</sup> daily), although this has not been rigorously proven. A minority of patients with BP respond poorly to such doses of systemic steroid; increasing the dose confers little additional benefit and is significantly more toxic.

It is not possible to identify a starting dose of prednisolone (or prednisone) that would be maximally effective and minimally toxic for all patients with BP. Doses which might meet these criteria for a majority of patients are:

1. 0.75–1 mg kg<sup>−1</sup> for patients with severe involvement;
2. 0.5 mg kg<sup>−1</sup> for moderate disease;
3. 0.3 mg kg<sup>−1</sup> for mild or localized disease.

If new inflammatory or blistered lesions are few or absent within 4 weeks, the treatment can be regarded as successful and the dose of steroid should then be gradually reduced. A reduction of the daily dose of prednisolone at fortnightly intervals, initially by about one-third or one-quarter down to 15 mg daily, then by 2.5 mg decrements down to 10 mg daily, is suggested. The dose could then be reduced by 1 mg each month. In about 50% of cases relapse will occur at some point during the dose-reduction period, indicating that the previous dose is likely to be the minimal effective dose for that patient.

For patients with widespread BP who do not respond to these doses, or who relapse on unacceptably high doses, other

Guidelines for the management of bullous pemphigoid 2012, V.A. Venning et al. 1203
agents, alone or in addition to the systemic steroid, may be preferable to higher doses of steroid.

The duration of systemic steroid treatment in BP is likely to be many months and is sometimes indefinite. Gastric protection, usually with a proton pump inhibitor, should be considered. Measures aimed at minimizing loss of bone density are appropriate in postmenopausal women and men over 50 years, and in any patient at increased risk of fragility fracture, who are expected to take prednisolone 7.5 mg or more daily for at least 3 months. Patients with BP (and also patients with pemphigus vulgaris) were reported to have lower levels of vitamin D, and a higher incidence of severe hypovitaminosis D, than controls, suggesting additional risk of bone density loss. Calcium and vitamin D supplementation and a bisphosphonate are usually recommended and have been shown to be effective in preserving bone density, if given from the start of systemic steroid therapy in patients with immunobullous diseases. Calcium may impair absorption of mycophenolate mofetil (MMF) and oral bisphosphonates and should be taken at a different time.

8.2 Topical corticosteroids (strength of recommendation A; level of evidence 1+)

Uncontrolled studies have suggested the successful use of topical steroids as first-line treatment for both localized and moderate disease, and two recent RCTs with a total of 653 participants confirmed this view.

Topical clobetasol propionate 0.05% cream (20 g) applied all over twice daily, including clinically unaffected skin (total daily dose 40 g), was compared with oral prednisone (1 mg kg\(^{-1}\) daily) in the treatment of BP. A significant benefit of the former was shown in extensive disease (more than 10 new blisters a day) for disease control, adverse events and mortality. In the moderate-disease group (fewer than 10 new blisters a day) no significant differences were found between clobetasol propionate cream and prednisone 0.5 mg kg\(^{-1}\) daily for disease control, adverse events and mortality. Morbidity and mortality attributable to corticosteroid treatment were seen in all groups but were significantly higher in the prednisone 1 mg kg\(^{-1}\) group.

In 2009 the same group compared clobetasol propionate cream 20 g twice a day (standard regimen) with 10–30 g per day depending on disease severity and body weight (mild regimen). Regression or healing of skin lesions at 3 weeks was achieved by nearly all patients in both regimens. The median cumulative doses of steroid cream used during the study period were 5760 g in the standard regimen vs. 1314 g in the mild regimen, which is a 70% reduction in cumulative doses. There was no difference regarding the relapses between the mild and standard regimens, indicating no significant difference in effectiveness between them.

The main severe side-effects in both groups were diabetes mellitus (n = 34 standard, n = 18 mild), cardiovascular and neurovascular disorders (n = 35 standard, n = 21 mild), and severe infections (n = 32 standard, n = 27 mild). There were also cutaneous side-effects, which included purpura, severe skin atrophy and striae.

There was no significant difference between the two groups in terms of year 1 mortality rate. In the standard regimen, mortality was 38% (58/153) [moderate disease 32% (21/65), severe disease 42% (37/88)] and in the mild regimen it was also 38% (58/153) [moderate disease 28% (19/69), severe disease 46% (41/90)]. However, the report of the study gives an adjusted analysis (Cox model adjusted for age and Karnofsky score), after which a beneficial effect of the mild regimen was observed in participants with moderate BP, with an almost twofold decrease in the risk of death or life-threatening adverse events relative to the standard regimen (hazard ratio 0.54, 95% confidence interval 0.30–0.97; \(P = 0.039\)).

A recent survey of 1135 dermatologists in the U.K. (326 responses, 28.7%) showed that 98% of respondents use topical steroids as sole treatment in localized BP and 34% in generalized BP. It is routinely used as an adjunct (92%), mostly applied to the lesions only (86%). A total of 34% of respondents use topical steroids until remission is achieved while 66% continue to use it to deal with relapses. All quoted percentages are based on valid responses.

Very potent topical steroids (clobetasol propionate) are an effective treatment for BP and they seem to have less serious adverse effects compared with 1 mg kg\(^{-1}\) of prednisone per day. However, their use in extensive disease may be limited by practical factors (e.g. ability of patient or availability of carer to apply the treatment) and they may be associated with systemic absorption and adverse events. When feasible they should be considered for first-line treatment, especially in localized disease.

8.3 Azathioprine (strength of recommendation D; level of evidence 4)

After systemic steroids, azathioprine is still a commonly used drug in BP. It is mostly employed in doses of up to 2.5 mg kg\(^{-1}\) daily as an adjunct to systemic steroids for its presumptive steroid-sparing effect. However, the efficacy of azathioprine as an adjunct to prednisolone in BP has been addressed in only two RCTs and with conflicting results. One small, nonblinded RCT reported a 45% reduction in cumulative prednisolone dosage over a 3-year period. Conversely, a larger RCT lasting only 6 months found no difference in remission rates in patients treated with steroids alone compared with those receiving combination treatment with prednisolone and azathioprine. In fact, more adverse effects were reported in patients receiving azathioprine.

A more recent nonblinded RCT with 73 patients compared azathioprine (2.0 g kg\(^{-1}\) daily) with MMF 1 g twice daily as adjuncts to methylprednisolone (0.5 mg kg\(^{-1}\) daily). Remission was achieved in 100% of patients in both groups but this trial included no steroid-only arm, so no conclusions can be drawn as to the superiority of adjunctive treatment over steroids alone. The azathioprine arm was slightly faster to produce remission than MMF (median 28.6 days compared...
with 42 days). Both treatments were similarly effective at preventing relapses and had similar numbers of adverse events. Hepatotoxicity was documented in six out of 37 patients treated with azathioprine but more infections occurred with MMF.\(^5\)\(^3\)\(^,\)\(^4\)\(^3\) Although the treatments were equally effective, the 5.5-fold higher cost of MMF (2 g daily) compared with azathioprine (2 mg kg\(^{-1}\) daily for a 75-kg patient) could be an important consideration in some health economies.

Azathioprine dose can be optimized with regard to myelo-suppression risk by prior assay of thiopurine methyltransferase (TPMT) activity, a test that is now widely available in the U.K. and relatively inexpensive.\(^4\)\(^4\) However, a normal TPMT level does not totally preclude myelotoxicity and regular monitoring of blood counts and liver function are essential.

There is currently insufficient evidence of benefit to recommend routine addition of azathioprine to systemic steroids for the control of BP. In view of its side-effect profile, it is recommended that azathioprine only be considered as an adjunctive treatment to prednisolone where response has been inadequate and the disease is not suppressed, or where the side-effects of existing therapy are troublesome and unacceptable.

### 8.4 Anti-inflammatory antibiotics and nicotinamide (strength of recommendation D; level of evidence 4)

Since the development of the last guideline in 2002 there have been no additional relevant publications regarding the treatment of BP with antibiotics. However, antibiotics with anti-inflammatory effects are used widely in the treatment of BP. A German survey reported that about 10% of the dermatologists use a combination of antibiotics and nicotinamide as a first-line treatment for BP;\(^3\)\(^5\) a survey in the U.K. showed that 80% of respondents use antibiotics as part of their management of BP.\(^4\)\(^0\) Mostly doxycycline is used in the U.K. (40%), followed by minocycline (31%) and lymecycline (19%). A total of 63% of respondents thought that antibiotics are sometimes effective, while 28% thought that they are never effective (all quoted percentages for the U.K. survey are based on valid responses).\(^4\)\(^0\)

The most reported side-effect was gastrointestinal upset, followed by pigmentation and Candida infection; hypersensitivity syndrome with hyper eosinophilia was only mentioned in two responses. An RCT is under way, comparing doxycycline (200 mg daily) with prednisolone (0.5 mg kg\(^{-1}\) daily) for the initial treatment of BP; the results are expected in 2013 (http://www.ukdctn.org/ongoing/blister/).

There are one small RCT,\(^4\)\(^6\) small uncontrolled trials and case reports on antibiotics and nicotinamide (nicotinamide). The small RCT compared six patients who received prednisolone (40–80 mg daily) with 14 patients who received tetracycline 2 g per day and nicotinamide 1500 mg daily. After 8 weeks of treatment there were one complete and five partial responders in the steroid group, compared with five complete responders, five partial responders, one nonresponder and one disease progression in the tetracycline group. Two participants in the tetracycline group were unavailable for follow-up at 8 weeks; the results were not statistically significant. Of the participants available for long-term follow-up, all five in the tetracycline group remained disease free (mean 17.5 weeks) while two of the three in the steroid group had repeated flares with tapered-off treatment (mean 21.3 weeks). The side-effect profile was in favour of tetracycline and nicotinamide. There are several additional case reports and small series that describe the beneficial effect of tetracyclines, usually in combination with nicotinamide. It was helpful in the majority within 1–3 weeks; however, some patients received topical or even systemic corticosteroids in addition.\(^4\)\(^6\)\(^–\)\(^5\)\(^2\)

There are only two case series involving 11 and 15 patients, and many case reports, of the beneficial effect of erythromycin in children and adults.\(^5\)\(^3\)–\(^5\)\(^5\) Erythromycin should be considered for treatment, particularly in children (adult dose 1000–3000 mg daily), and perhaps in combination with topical corticosteroids. A beneficial effect may be seen within 1–3 weeks of commencing treatment.

In conclusion, tetracyclines and nicotinamide may be considered as treatment in adults, perhaps in combination with topical corticosteroids. However, apart from one case report of niacinamide (nicotinamide) as monotherapy in localized BP, there is no evidence for its effectiveness as a sole treatment of BP.\(^5\)\(^6\)

8.5 Methotrexate (strength of recommendation D; level of evidence level 4)

There are no controlled trials involving methotrexate (MTX) for the treatment of BP. Two small prospective case series of 11 and 16 patients both reported that relatively low doses of MTX (max. 15 mg weekly) can be effective at controlling BP, either as a monotherapy\(^5\)\(^7\) or in combination with topical steroids.\(^5\)\(^8\) This was confirmed by a recent retrospective multicentre case series of 70 patients treated with MTX alone, or in combination with topical steroids.\(^5\)\(^9\)

The largest retrospective analysis\(^6\)\(^0\) compared 138 consecutive patients: 61 patients received MTX plus concomitant topical steroids (2.5–17.5 mg per week, median dose 5 mg per week); 37 patients received MTX and prednisolone plus concomitant topical steroids until cessation of new blisters; 15 patients received
prednisolone only (6–40 mg daily, median dose 12 mg daily) owing to pre-existing contraindications or adverse effects with MTX, or because of physician or patient preference; 25 patients were treated with topical betamethasone gel only.

The 2-year remission was 43% for MTX, 35% for MTX and prednisolone, 0% for prednisolone and 83% for the topical steroid group. Remission occurred after a median treatment time of 11 (MTX), 20 (MTX and prednisolone) and 2 months (topical steroid). The median cumulative MTX dose to achieve remission was 210 mg (range 20–1350 mg). Being retrospective, the cases were unmatched for disease severity and there appears to be a higher proportion of mild cases in the patients receiving MTX as monotherapy. MTX was discontinued in five patients because of adverse effects (gastrointestinal symptoms, anaemia, liver dysfunction and alveolitis). Increasing age was significantly associated with decreasing survival, but there was no significant difference between the various treatments and survival rates.60

The most important toxicities of MTX are myelosuppression, hepatotoxicity and pneumonitis. MTX is excreted renally, which should be considered in the elderly and may explain the low doses required for disease control.61 Many investigators recommend folic acid 5 mg on the non-MTX days to reduce some adverse effects, but this is not proven.

Evidence from these case series suggests that MTX can be effective at controlling BP, either as a monotherapy or in combination with topical or systemic steroids.

### 8.6 Mycophenolate mofetil (level of evidence 1)

MMF is an inhibitor of purine synthesis in activated T and B cells and is a generally well-tolerated immunosuppressive agent used in the prevention of renal graft rejection since 1997. It has been reported as effective in controlling BP in doses of 0.5–1 g twice daily in a small number of individual case reports, both as an adjunct to systemic prednisolone62 and as a monotherapy following disease relapse.63

In a nonblinded RCT including 73 patients, MMF (1 g twice daily) was compared with azathioprine (2 g kg\(^{-1}\) daily) as an adjunct to methylprednisolone (0.5 mg kg\(^{-1}\) daily).62 This trial did not include a steroid-only arm so no conclusions can be drawn as to the superiority of either adjunctive treatment over corticosteroids as a monotherapy. There was no difference between the two treatments, although MMF was slightly slower to produce remission than azathioprine (median 42 days compared with 28.6 days). Both treatments were associated with similar numbers of adverse events, with MMF being associated with more infections but less hepatotoxicity than azathioprine.42,43 As discussed in section 8.3, MMF is considerably more costly than azathioprine. Further evidence is needed for the role of MMF in BP.

### 8.7 Dapsone and sulfonamides (strength of recommendation D; level of evidence 3)

There are no RCTs with respect to the use of either dapsone or sulfonamides, either as sole treatments or as adjuncts in the management of BP. Four retrospective series covering a total of 110 patients have reported experience with dapsone 50–200 mg daily or (rare cases) with either sulfapyridine or sulfamethoxypyridazine 1–1.5 g daily. These were employed either as sole treatments or in combination with topical steroids. The response rate was around 45% in three series,64–66 but only 15% (six of 41) in the fourth.67 Response seems to be slower in onset than with systemic steroids. A single, small, uncontrolled series reported a possible steroid-sparing effect in patients in whom dapsone was added to existing treatment with prednisolone and azathioprine.68 Another series of 62 patients reported a complete remission rate of 32% at 2 weeks in patients treated with dapsone 0.5–1.0 mg kg\(^{-1}\) daily in combination with systemic methylprednisolone 0.5 mg kg\(^{-1}\) daily and topical steroids. The series was retrospective with no comparator arm so no conclusion was possible as to whether there was any steroid-sparing effect.69

There are individual case reports of dapsone (either alone or with oral steroids) used successfully in childhood BP.70,71

Glucose-6-phosphate dehydrogenase deficiency predisposes to haematological side-effects and should be excluded in predisposed races (e.g. those of African, Middle Eastern and South Asian origin), and all patients receiving dapsone need very frequent monitoring of blood count and liver function in the early months. The side-effect profile of dapsone and sulfonamides is potentially hazardous in the elderly. In this age group, these treatments should be considered only if other treatments are ineffective or contraindicated, and treatment started at low doses (50 mg daily) to be increased by 50 mg daily in 2-weekly steps to a maximum of 150–200 mg daily.

### 8.8 Intravenous immunoglobulins (strength of recommendation D; level of evidence 3)

Intravenous immunoglobulin (IVIg) has been widely tried as an immunomodulatory agent in various autoantibody-mediated blistering diseases. Excluding cases of MMP, experience in BP is confined to a total of fewer than 41 patients in small retrospective series and case reports.72–77 When used as a sole treatment, some patients achieved rapid and dramatic, albeit short-lived responses, with relapse occurring within 2 weeks, necessitating either further infusion or treatment with corticosteroids or azathioprine.72,73,77 IVIg has been more commonly used concomitantly with oral prednisolone and other agents.75,77 A retrospective case series reported on 15 patients with severe, unstable steroid-dependent pemphigoid or in whom there were significant treatment side-effects, and other immunosuppressants or immunomodulatory agents had failed. Treatment was with polyvalent immunoglobulin 2 g kg\(^{-1}\) administered in equally divided doses over 3 days and overlapping with preceding treatments. Treatment cycles were repeated initially every 4 weeks until remission, and thereafter with intervals between cycles gradually increasing. The IVIg permitted gradual withdrawal of prednisolone over 1–5 months in all 15 patients. The report does not make clear whether all other potentially active agents were also
withdrawn. Remission was maintained over a further 17–
26.5 months with a mean of 14.9 further cycles of IVIg. 

IVIg is well tolerated but expensive, costing £5320–00 per
cycle of 2 g kg⁻¹ in a 70-kg patient. U.K. guidance on its
use is available from the Department of Health (http://
www.dh.gov.uk). IVIg should only be considered as an
adjunctive treatment in patients with very severe disease where
rapid control is needed, or when there is failure with or con-
traindication to other treatments.

8.9 Chlorambucil (strength of recommendation D; level
of evidence 3)

In an open study, 23 patients with BP completed treatment
with initial doses of prednisolone of 40–60 mg daily and chlorambu-
cil approximately 0.1 mg kg⁻¹ daily. After 2 weeks, the doses
of both drugs were gradually reduced. All patients responded
and none required treatment for more than 12 months. The
maintenance dose of chlorambucil after 6 weeks was 2 mg per
day in most cases. The mean total steroid requirement was
1866 mg, about 50% of that previously reported for prednisone
and azathioprine (3688 mg over 3 years).

The risk of haematological toxicity, especially thrombocyto-
penia, was emphasized, and blood counts were initially moni-
tored weekly. One patient discontinued chlorambucil due to
marrow suppression, which recovered after discontinuation.
Haematological malignancy has been attributed to chlorambu-
cil and the authors suggest that a cumulative dose of 1 g, or
treatment duration of 1 year, should not be exceeded.

In a second study from the same centre, a retrospective
comparison was made between patients with BP treated with
prednisolone alone (26 patients), and those treated with pred-
nisolone and chlorambucil (19 patients). The dose of pred-
nisolone was 20–60 mg daily based on disease severity and
patient size, reduced according to response. Chlorambucil was
started at about 0.1 mg kg⁻¹ daily (0.05 mg kg⁻¹ daily in
‘very elderly’ patients or if the platelet count was
<250 x 10⁸ L⁻¹). After 2 weeks it was reduced to
0.05 mg kg⁻¹ daily, and after a further 4 weeks to 2 mg daily.
The mean cumulative dose of prednisolone (2685 vs.
4074 mg), and the mean duration of therapy (215 vs.
392 days), were both statistically significantly lower in the
chlorambucil group. Apart from an asymptomatic reduction in
platelet count below the normal range in one patient, no
adverse effects were attributed to chlorambucil.

Chlorambucil as an adjunct to systemic steroids should be
considered as an alternative to other more established immu-
nosuppressants if these have failed or are poorly tolerated or
contraindicated. Careful monitoring is required for possible
haematological toxicity.

8.10 Cyclophosphamide

Three cases have been reported in which cyclophosphamide
appeared to have a beneficial effect in otherwise refractory
BP. In the only case series detailing the effects of cyclophos-
phamide in BP, 10 patients were treated with systemic ste-
roid in doses of 1–1.9 mg kg⁻¹ daily prednisone equivalent
and with cyclophosphamide 100 mg daily. Three patients,
who had medical comorbidities, died; four others suffered
significant adverse effects involving marrow toxicity and sep-
ticemia. Comparing their results with published studies, the
authors did not perceive a steroid-sparing effect with the
cyclophosphamide, but they had no control cases on steroid
alone.

Cyclophosphamide is more toxic than other immunosup-
pressive drugs used for BP. It may rarely be considered for
exceptionally refractory disease.

8.11 Ciclosporin

Reported experience of the use of ciclosporin in BP is limited
to two reports from the same centre with overlapping cases,
comprising a total of seven patients treated with high doses of
6–8 mg kg⁻¹ daily. Good responses were seen in two out of
four cases treated with ciclosporin alone. Three patients who
had relapsed on prednisone responded to the addition of
ciclosporin, and two of these relapsed after the ciclosporin
was discontinued. Elevation of serum creatinine occurred in
most of the patients (details not given) but was reported to be
‘significant’ in only one.

Ciclosporin cannot be recommended in the routine treat-
ment of BP. It may rarely have a place in refractory cases but
its value is likely to be limited by renal toxicity, especially in
the elderly.

8.12 Other treatments

8.12.1 Topical tacrolimus (strength of recommendation D;
level of evidence 3)

Individual case reports have described a response to topical
treatment with the calcineurin inhibitor, tacrolimus. It has
mainly been used for localized and limited generalized dis-
ease. Chu et al. reported two cases of generalized disease
treated with multiple systemic agents including oral steroids
but not topical steroids. Application of tacrolimus ointment
0.1%, 3–5 g daily, allowed reduction of oral steroids and
improvement was seen within 2 weeks, although follow-up
data were not reported. In a case of mild vesicular pemphig-
oid, reduction of oral steroids and use of potent topical ste-
roids led to new vesicles; these ceased with the substitution
of topical steroids with tacrolimus ointment 0.1% (twice
daily for 2 weeks), allowing withdrawal of the oral ste-
roids. In other reports, topical tacrolimus has been used as
the sole agent for localized disease and also in vulval pem-
phigoid in a child. The use of topical tacrolimus is lim-
ited by local irritation and its price compared with topical
steroids. It may be useful as an alternative in localized and
limited disease without the disadvantage of causing skin
atrophy.
8.12.2 Biologic agents

Only a few reported cases of BP have been treated with tumour necrosis factor-α antagonists and the anti-CD20 agent, rituximab. The outcome is variable and success is limited by significant adverse events.

Rituximab (strength of recommendation D; level of evidence 3) This chimeric murine–human monoclonal antibody targets CD20, the B cell-specific cell surface antigen, following which B cells may be depleted from the circulation for 6–12 months. Only a few reported patients including two children with BP have been treated with rituximab.92–98 The dosing regimen in most cases was a weekly infusion (375 mg m⁻²) for 4 weeks, followed by repeat infusion in some cases; improvement was usually seen after 4 weeks. All treated cases had refractory disease and all but two were treated concurrently with other immunosuppressants. Rituximab was used as a monotherapy in two cases with concomitant BP and chronic lymphocytic leukaemia with good initial outcome but no reported follow-up data.94 In general, rituximab allowed gradual withdrawal of other immunosuppressants and led to disease remission, although serious adverse events were seen in three of eight cases. Two patients died 6 weeks and 2 years after the treatment from nosocomial pneumonia and bacterial sepsis, respectively, and a 2-year-old boy was left with persistent hypogammaglobulinaemia following a series of infections.92,95

Antitumour necrosis factor-α agents (strength of recommendation D; level of evidence 3) There are no trials or large case series, and there is conflicting evidence as to whether these agents treat or induce BP. Etanercept was used successfully in the treatment of a patient with BP and psoriasis,99 but in another case, long-term use of etanercept for rheumatoid arthritis was thought to have induced BP.10 Two other reports describe adalimumab-induced BP, one with features overlapping with MMF.100,101

Other biologic agents (strength of recommendation D; level of evidence 3) Omalizumab, a humanized monoclonal antibody that inhibits IgE binding, was used successfully to treat one infant and one adult with refractory BP but with no reported follow-up data for the adult case.102,103 A monoclonal antibody to interleukin-2 receptor of T cells (daclizumab, anti-CD25) has been used to treat a patient with BP, and in combination with rituximab in a patient with BP and concomitant graft-versus-host disease (GVHD).95,104 Additional immunosuppressive treatment was needed in the first patient, and the patient with GVHD, although cleared of blisters, died after a year with sepsis. Daclizumab is no longer produced.

Biological drugs are expensive and may be associated with potentially serious adverse effects; until further supportive evidence is available, their role in BP remains limited.

8.12.3 Plasmapheresis and immunoapheresis (strength of recommendation D; level of evidence 3)

One RCT27 showed an apparent steroid-sparing effect with plasmapheresis (plasma exchange) whereas another RCT did not.29 Other small case series and anecdotal case reports have used different regimens of treatment with varying outcomes.105–107 A child with BP and inflammatory bowel disease was treated with plasma exchange in combination with extracorporeal photochemotherapy that allowed reduction of immunosuppressive agents.105

Immunoapheresis is a procedure by which immunoglobulins are removed from the circulation without the need to replace the plasma. Only a few case reports108–110 describe immunoapheresis as an adjuvant treatment for BP, allowing remission with a reduced dose of systemic steroids.

Plasmapheresis and immunoapheresis have no role in the routine treatment of BP, although in cases of refractory BP or when reduction of immunosuppressive drugs is necessary due to intolerance and adverse effects, these modalities may be used as adjuvant treatment.

9.0 Childhood bullous pemphigoid

BP is rare in childhood and infancy. It may mimic the adult disease but there may be a greater predilection for involvement of the palms and soles in infants; localized vulval involvement is well recognized in later childhood. Childhood pemphigoid may be short-lived, remitting in weeks or months.111,112 Owing to its rarity, there are no trials covering childhood or infantile cases. The most commonly used treatment is prednisolone 1 mg kg⁻¹ daily, increasing to 2 mg kg⁻¹ daily in some cases.112 Other treatments with reported benefit are potent topical steroids alone, erythromycin as monotherapy or with nicotinamide, as well as sulfapyridine and dapsone, both as sole treatment, or with prednisolone.70,71,112,113 There are a small number of case reports for the use of IVIg,114,115 MMF,116 and in two separate cases of severe recalcitrant disease in infancy, rituximab was effective in one93 and subcutaneous omalizumab in another.103

Although there is no evidence to support any particular treatment strategy in childhood and infantile BP, its generally short-lived and benign nature suggests that preference should be given to low-toxicity treatments such as erythromycin and topical steroids (strength of recommendation D; level of evidence 3).

10.0 Skin care in bullous pemphigoid

There are no studies on this topic and the following recommendations are based on the personal experience of the authors. Blisters should generally be left intact if possible as this may help prevent secondary bacterial infection. When they are particularly large or in sites where they are troublesome or interfere with function, such as the sole of the foot, blisters may be pierced with a sterile needle releasing the fluid, but leaving the blister roof in place. If there are extensive areas of erosion and open raw areas, antiseptics such as potassium permanganate as a bath or soaks, or antiseptic-containing bath oils [e.g. Dermol 600® (Dermal Laboratories, Hitchin, U.K.) or Oilatum Plus® (Steifel Laboratories, High Wycombe, U.K.)] may be used for a few days to dry the lesions and prevent infection. Painful eroded or raw areas may be covered with a low-adhesion dressing such as Mepitel® (Molnlycke, Dunstable, U.K.) or Atrament® (Hartmann, Heywood, U.K.) held in place with soft elasticated viscose
stockinette [e.g. Comfifast® (Synergy, Swindon, U.K.), Tubifast® (Mohnlycke)]. It is important to ensure that such areas of erosion are included in treatment with topical steroids (clobetasol propionate) [Strength of recommendation D (good practice point)].

11.0 Follow-up

BP is frequently a chronic disease and ideally patients should be followed until they are in complete remission and off all treatment. Patients should be monitored for drug side-effects and to ensure that symptoms are controlled to their satisfaction without excessive doses of topical or systemic treatment. Occasional itching or lesions (if acceptable to the patient) indicates that they are not being overtreated. Once their disease is stable, an attempt should be made to wean treatment at roughly 2–4 weekly intervals; this should be done on clinical criteria rather than by IF testing.

12.0 Future directions

Despite being the commonest of the autoimmune blistering diseases in many parts of the world, the evidence base for optimum treatment is relatively incomplete and patchy. Important questions that remain to be addressed include the following.

12.1 Systemic steroids

1 What is the optimum starting dose of oral prednisolone, 0·3, 0·5 or 1·0 mg kg⁻¹ daily?
2 How might the starting dose be stratified for disease of different severity?
3 The ideal protocol for weaning oral steroids has not been clarified so as to minimize cumulative dosage while maintaining disease control.
4 At what level of steroid requirements should a second drug or a change in treatment be considered?

12.2 Topical corticosteroids

1 Topical steroids have a good evidence base for efficacy but are used in many different ways and it is not known which method is most effective. Is the optimum use of topical steroids as an adjunct to other treatments? Should they be used as a monotherapy?
2 Clobetasol propionate 20 g twice daily when applied to the whole skin surface, including unaffected skin, undoubtedly has efficacy but also toxicity, as well as practical difficulties in application. Would similar benefits be obtained using topical steroids applied to lesional skin only?
3 For what severity of disease might the above approach be recommended?

12.3 Anti-inflammatory antibiotics

Anti-inflammatory antibiotics are widely used and may be a safer treatment than systemic steroids for some patients. The BLISTER trial, comparing prednisolone 0·5 mg kg⁻¹ daily with doxycycline 200 mg daily, is currently in progress and is expected to report in 2013 (http://www.ukdctn.org/ongoing/blister/). If tetracyclines are of benefit, does that apply equally to all drugs of this class, and what are the optimal dose(s) considering both efficacy and adverse effects?

12.4 Azathioprine, methotrexate, dapsone and chlorambucil

Although there is some evidence to support the use of azathioprine, MTX, dapsone and chlorambucil, there is not yet conclusive evidence of a steroid-sparing effect with any of these agents.

12.5 Patient stratification

BP is a heterogeneous disease both clinically and immunopathologically. However, it is not possible to define reliably subgroups in which more aggressive treatment may be justified. ELISA titres to the immunodominant NC16A epitope correlate with disease activity but it is unknown whether titres predict response to treatments. Other means of stratifying patients for prognosis and responsiveness to specific treatment are needed.

12.6 Results of other clinical trials

In addition to the current RCT comparing doxycycline with oral prednisolone for BP, several other clinical trials investigating the effect of rituximab, leflunomide associated with topical corticosteroids, and NPB-01 (IVIg) are under way or being planned.

13.0 Recommended audit points

1 In the last five consecutive patients seen with BP, is there clear documentation of the relevant and important comorbidities of diabetes and hypertension?
2 In the last five consecutive patients seen with BP in whom there was intention to treat with oral corticosteroid, did they receive provision for bone protection?
3 In the last five consecutive patients seen with BP and treated, is there evidence of the patients’ satisfaction with the outcome of the treatment on control of their symptoms?
4 In the last five consecutive patients who were treated with systemic medication for BP, was there a clear documentation of pretreatment tests (such as full blood count, liver function tests, glucose, renal function, blood pressure) and appropriate tests during follow-up?

14.0 Summary

Details of evidence are given in the text. BP is a serious disease, causing considerable distress from the symptoms of itching and blistering; when severe it is potentially life-threatening. Good disease control is therefore essential. Both disease
severity and patient comorbidities, including the ability to use topical treatments effectively, must be taken into consideration. There are few rigorous RCTs or other high-quality evidence to inform treatment choice. There is some evidence to support the treatments discussed below, which are also summarized in Table 2.

Both systemic and topical steroids have good evidence of efficacy and remain the most widely used first-line treatments. Topical steroids may be used as an adjunct to any other treatment or used as a monotherapy, either locally applied to lesions (for localized disease) or all over the skin (if feasible) as an alternative to systemic steroids. Anti-inflammatory antibiotics have a smaller evidence base for efficacy (trial data expected in 2013) but are widely used and may be a safer treatment for patients with comorbidities of diabetes or hypertension, and for children. There is some evidence to support the use of azathioprine, MTX, dapsone and chlorambucil.

### Acknowledgments

We are very grateful to Prof. Hywel Williams (BLISTER trial; Queen’s Medical Centre, Nottingham), Miss Lesley Exton (BAD Information Scientist), Miss Sara Haveron (BAD Scientific Administrator), Dr Catherine Smith (St John’s Institute of Dermatology, London) and Dr Simon Meggitt (Royal Victoria Infirmary, Newcastle), as well as the BDNG, PCDS and Pemphigus Vulgaris Network.
